## CS 383: Artificial Intelligence

#### Markov Decision Processes

#### Prof. Scott Niekum, UMass Amherst

[These slides based on those of Dan Klein and Pieter Abbeel for CS188 Intro to AI at UC Berkeley. All CS188 materials are available at http://ai.berkeley.edu.]

#### Non-Deterministic Search

## Example: Grid World

- A maze-like problem
  - The agent lives in a grid
  - Walls block the agent's path
- Noisy movement: actions do not always go as planned
  - 80% of the time, the action has the intended effect (if there is no wall there)
  - 20% of the time an adjacent action occurs instead. Ex: North has 10% chance of East and 10% chance of West
  - If there is a wall in the direction the agent would have been taken, the agent stays put
- The agent receives rewards each time step
  - Small "living" reward each step (can be negative)
  - Big rewards come at the end (good or bad)
- Goal: maximize sum of rewards

## Grid World Actions

#### Stochastic Grid World

#### **Markov Decision Processes**

- An MDP is defined by:
  - A set of states s ∈ S
  - A set of actions a ∈ A
  - A transition function T(s, a, s')
    - Probability that a from s leads to s', i.e., P(s' | s, a)
    - Also called the model or the dynamics
  - A reward function R(s, a, s')
    - Sometimes just R(s) or R(s')
  - A start state
  - Maybe a terminal state
- MDPs are non-deterministic search problems
  - One way to solve them is with expectimax search
  - ...but with modification to allow rewards along the way
  - We'll have a new, more efficient tool soon

## What is Markov about MDPs?

- "Markov" generally means that given the present state, the future and the past are independent
- For Markov decision processes, "Markov" means action outcomes depend only on the current state

$$P(S_{t+1} = s' | S_t = s_t, A_t = a_t, S_{t-1} = s_{t-1}, A_{t-1}, \dots, S_0 = s_0)$$

$$P(S_{t+1} = s' | S_t = s_t, A_t = a_t)$$

 This is just like search, where the successor function could only depend on the current state (not the history)

Andrey Markov (1856-1922)

# Policies

- In deterministic single-agent search problems, we wanted an optimal plan, or sequence of actions, from start to a goal
- For MDPs, we want an optimal policy  $\pi^*: S \rightarrow A$ 
  - A policy  $\pi$  gives an action for each state
  - An optimal policy is one that maximizes expected utility if followed
  - An explicit policy defines a reflex agent
- Expectimax didn't compute entire policies
  - It computed the action for a single state only

Optimal policy when R(s, a, s') = -0.03 for all non-terminals s

## **Optimal Policies**

R(s) = -0.01

R(s) = -0.03

R(s) = -2.0

## Example: Racing

## Example: Racing

- A robot car wants to travel far, quickly
- Three states: Cool, Warm, Overheated
- Two actions: *Slow*, *Fast*

#### **MDP Search Trees**

#### **Utilities of Sequences**

## **Utilities of Sequences**

- What preferences should an agent have over reward sequences?
- More or less? [1, 2, 2] or [2, 3, 4]
- Now or later? [0, 0, 1] or [1, 0, 0]

# Discounting

- It's reasonable to maximize the sum of rewards
- It's also reasonable to prefer rewards now to rewards later
- One solution: values of rewards decay exponentially

# Discounting

- How to discount?
  - Each time we descend a level, we multiply in the discount once
- Why discount?
  - Sooner rewards probably do have higher utility than later rewards
  - Also helps our algorithms converge
- Example: discount of 0.5
  - U([1,2,3]) = 1\*1 + 0.5\*2 + 0.25\*3
  - U([1,2,3]) < U([3,2,1])</li>

## **Stationary Preferences**

Theorem: if we assume stationary preferences:

$$[a_1, a_2, \ldots] \succ [b_1, b_2, \ldots]$$

$$(r, a_1, a_2, \ldots] \succ [r, b_1, b_2, \ldots]$$

- Then: there are only two ways to define utilities
  - Additive utility:  $U([r_0, r_1, r_2, \ldots]) = r_0 + r_1 + r_2 + \cdots$
  - Discounted utility:  $U([r_0, r_1, r_2, \ldots]) = r_0 + \gamma r_1 + \gamma^2 r_2 \cdots$

# Quiz: Discounting

Given:

- Actions: Left, Right, and Exit (only available in exit states a, e)
- Transitions: deterministic
- Quiz 1: For  $\gamma = 1$ , what is the optimal policy?

- 10 1
- Quiz 2: For  $\gamma$  = 0.1, what is the optimal policy?
- Quiz 3: For which γ are Left and Right equally good when in state d?

 $10 g^3 = 1 g \longrightarrow g = sqrt(1/10)$ 

# Infinite Utilities?!

- Problem: What if the game lasts forever? Do we get infinite rewards?
- Solutions:
  - Finite horizon: (similar to depth-limited search)
    - Terminate episodes after a fixed T steps (e.g. life)
    - Gives nonstationary policies (π depends on time left)
  - Discounting: use  $0 < \gamma < 1$

$$U([r_0, \dots r_\infty]) = \sum_{t=0}^{\infty} \gamma^t r_t \le R_{\max}/(1-\gamma)$$

- Smaller γ means smaller "horizon" shorter term focus
- Absorbing state: guarantee that for every policy, a terminal state will eventually be reached (like "overheated" for racing)

## Recap: Defining MDPs

- Markov decision processes:
  - Set of states S
  - Start state s<sub>0</sub>
  - Set of actions A
  - Transitions P(s'|s,a) (or T(s,a,s'))
  - Rewards R(s,a,s') (and discount γ)

- Policy = Choice of action for each state
- Utility = sum of (discounted) rewards

## Solving MDPs

## **Optimal Quantities**

- The value (utility) of a state s:
  - V\*(s) = expected utility starting in s and acting optimally
- The value (utility) of a q-state (s,a):
  - Q\*(s,a) = expected utility starting out having taken action a from state s and (thereafter) acting optimally
- The optimal policy:

 $\pi^*(s)$  = optimal action from state s

## Gridworld Q Values

### Values of States

Fundamental operation: compute the (expectimax) value of a state

- Expected utility under optimal action
- Average sum of (discounted) rewards
- This is just what expectimax computed!

#### Recursive definition of (optimal) value:

$$V^{*}(s) = \max_{a} Q^{*}(s, a)$$
$$Q^{*}(s, a) = \sum_{s'} T(s, a, s') \left[ R(s, a, s') + \gamma V^{*}(s') \right]$$
$$V^{*}(s) = \max_{a} \sum_{s'} T(s, a, s') \left[ R(s, a, s') + \gamma V^{*}(s') \right]$$

- We're doing way too much work with expectimax!
- Problem: States are repeated
  - Idea: Only compute needed quantities once
- Problem: Tree goes on forever
  - Idea: Do a depth-limited computation, but with increasing depths until change is small
  - Note: deep parts of the tree eventually don't matter if γ < 1</li>

## **Time-Limited Values**

- Key idea: time-limited values
- Define V<sub>k</sub>(s) to be the optimal value of s if the game ends in k more time steps
  - Equivalently, it's what a depth-k expectimax would give from s

### **Computing Time-Limited Values**

## Value Iteration

# Value Iteration

- Start with  $V_0(s) = 0$ : no time steps left means an expected reward sum of zero
- Given vector of V<sub>k</sub>(s) values, do one step of expectimax from each state:

$$V_{k+1}(s) \leftarrow \max_{a} \sum_{s'} T(s, a, s') \left[ R(s, a, s') + \gamma V_k(s') \right]$$

- Repeat until convergence
- Complexity of each iteration: O(S<sup>2</sup>A)
- Theorem: will converge to unique optimal values
  - Basic idea: approximations get refined towards optimal values
  - Policy may converge long before values do

### **Example: Value Iteration**

 $Q_2(cool, fast) = 0.5(2+2) + 0.5(2+1) = 3.5$
