Abstract—Content delivery networks (CDNs) are an important class of Internet-scale distributed systems that deliver web, streaming, and application content to end users. A commercial CDN could comprise hundreds of thousands of servers deployed in over thousand clusters across the globe and incurs significant energy costs for powering and cooling their servers. Since energy costs are a significant component of the total operating expense of a CDN, we propose and explore a novel technique called cluster shutdown that turns off an entire cluster of servers of a CDN that is deployed within a data center. By doing so, cluster shutdown saves not just the power consumed by the servers but also the power needed for cooling those servers. We present an algorithm for cluster shutdown that is based on realistic power models for servers and cooling equipment and can be implemented as a part of the global load balancer of a CDN. We evaluate our technique using extensive real-world traces from a large commercial CDN to show that cluster shutdown can reduce the system-wide energy usage by 67%. Further, much of the energy savings are obtainable without sacrificing either bandwidth costs or end-user performance. In addition, 79% of the optimal savings are attainable even if each cluster is limited to at most one shutdown per day, reducing the required operational overhead. Finally, we argue that cluster shutdown has intrinsic architectural advantages over the well-studied server shutdown techniques in the CDN context, and show that it saves more energy than server shutdown in a wide range of operating regimes.

I. INTRODUCTION

Large Internet-scale distributed systems deploy hundreds of thousands of servers in thousands of data centers around the world. Such systems currently provide the core distributed infrastructure for many popular Internet applications that drive business, e-commerce, entertainment, news, and social networking. The energy cost of operating an Internet-scale system is already a significant fraction of the total cost of ownership (TCO) [1]. The environmental implications are equally important. A large distributed platform with 100,000 servers will expend roughly 190,000 MWH per year, enough energy to sustain more than 10,000 households. In 2005, the total data center power consumption was already 1% of the total US power consumption while causing as much emissions as a mid-sized nation such as Argentina. Further, with the deployment of new services and the rapid growth of the Internet, the energy consumption of data centers is expected to grow at a rapid pace of more than 15% per year in the foreseeable future [2]. These factors necessitate rearchitecting Internet-scale systems to include energy optimization as a first-order principle.

An important Internet-scale distributed system to have emerged in the past decade is the content delivery network (CDN, for short) that delivers web content, web and IP-based applications, downloads, and streaming media to end-users (i.e., clients) around the world. A large CDN, such as that of a commercial provider like Akamai, consists of hundreds of thousands of servers located in over a thousand data centers around the world and account for a significant fraction of the world’s enterprise-quality web and streaming media traffic today [3]. The servers of a CDN are deployed in clusters where each cluster consists of servers in a particular data center in a specific geographic location. The clusters are typically widely deployed on the “edges” of the Internet in most major geographies and ISPs around the world so as to be proximal to clients. Clusters can vary in size from tens of servers in a small Tier-3 ISP to thousands of servers in a large Tier-1 ISP.

The primary goal of a CDN is to serve content such as web pages, videos, and applications with high availability and performance to end users. The key component that ensures availability and performance is the CDN’s load balancing system that assigns each incoming request to a server that can serve that request. To this end, a CDN’s load balancing system routes each user’s request to a server that is live and not overloaded. Further, to enhance performance, a CDN ensures that each user request is routed to a server that is proximal to that user. The proximity (in a network sense) ensures that the network path between the user’s device and the CDN’s server has low latency and loss. The process of routing user requests to servers is a two stage process. A global load balancer (called GLB) assigns the user to a cluster of servers based on the availability of server resources in the cluster, performance, and bandwidth costs. A local load balancer (called LLB) assigns the user to a specific server that is capable of serving the requested content within the chosen cluster. The choice of server is dictated by server liveness, content footprint, and current server loads with respect to their capacities. A comprehensive discussion of the rationale and system architecture of CDNs is available in [3].

A. Cluster shutdown: a technique for energy reduction

A number of approaches are relevant to reducing the energy consumption of CDNs. In the past two decades, there has been significant work in improving the energy efficiency of servers and data centers. Such improvements yield energy savings in any deployed distributed system, including CDNs. For instance, the switch to multi-core architectures, the increasing use of SSDs, static power management (SPM) to decrease energy use when the servers are idle, use of low-power servers [4], and power scaling techniques such as Dynamic Voltage and Frequency Scaling (DVFS) [5], [6] all help reduce
CDN energy consumption. Similarly, the use of temperature controlled fans and advances in air flow management have led to increases in cooling efficiency[7], [8].

In addition to the above generic methods, there has been recent work on CDN-specific techniques that incorporate the ability to turn off individual servers during periods of low load to reduce the energy consumption [9]. Such a server shutdown technique is implemented within the local load balancer (LLB) of the CDN. The work in [9] shows that the availability, performance, and operational costs of the CDN remain unaffected when turning off servers to save energy.

In this paper, we propose and evaluate a novel CDN-specific technique called cluster shutdown where an entire cluster of servers in a CDN data center can be turned off. Cluster shutdown is easily integrated into the global load balancer (GLB) that will now have the ability to move all load away from a cluster and shut it down. However, since the granularity of energy management is to turn off entire clusters or leave them entirely on, the technique does not have the ability to turn off individual servers (e.g., a fraction of a cluster). In contrast, the server shutdown technique studied in [9] has the ability to shutdown individual servers within the cluster depending on the load, but has no ability to control how much load enters a cluster. Therefore, in this sense, the two techniques are complementary and may be implemented together. While cluster shutdown has not been studied before in the CDN context, it has certain natural advantages that make it worthy of consideration for CDN energy reduction.

(1) Redundant deployments. Large CDNs such as Akamai can have over a thousand clusters deployed in data centers around the world [3] with more than a dozen redundant deployments in any given geographical area. Thus, when some clusters near a user are shutdown during off-peak hours, other nearby active clusters can continue to provide CDN service to users and ensure good availability and performance. In fact, one of the contributions of this work is determining the impact of cluster shutdowns on user performance.

(2) Cluster shutdown is consistent with the original CDN architectural design. Each cluster in a CDN is often architected to be a self-sufficient unit with enough processing and disk storage to serve the content and application domains that are assigned to it [3]. In particular, there is limited data dependency and resource sharing across clusters. Thus, cluster shutdown can be implemented with little or no changes to the CDN’s original architecture. In contrast, servers within a cluster are closely linked in a fine-grained fashion and they cooperatively cache and serve the incoming requests. For instance, servers within the same cluster cooperatively store application state and content for user requests served by that cluster. Thus, shutting down individual servers for energy savings requires greater migration of state and content between servers in a cluster at levels not customary in a CDN today. Cluster shutdown, in contrast, does not require state migration and cached content is already replicated across clusters for fault-tolerance purposes, which ensures that availability is not impacted by shutting down a cluster. In this sense, cluster shutdown is a better architectural design choice for energy management than server shutdown.

(3) Cluster shutdown has the potential to save on cooling power in addition to IT power. A key advantage of cluster shutdown is that the all of the energy consumed by a cluster, which includes energy consumed by the servers, the network equipment, and the cooling within that cluster, can be saved when a cluster is turned off. In contrast, a server shutdown technique will typically turn off a fraction of the servers within the cluster and will require the networking and cooling equipment to stay on. The cooling equipment is not energy proportional—thus turning off a fraction of the servers only saves energy consumed by those servers and does not yield a proportionate reduction in cooling costs.

For cluster shutdown to be effective, a CDN would need to have control over all of its energy consumption, i.e., both IT (such as servers) and cooling equipment. Such a scenario is reasonable given the trend for CDN’s to opt for self-contained, modular [10], or containerized [11] deployments. With such deployments a CDN can manage the power consumption of its own cluster, independent of other tenants in the data center – an advantage for a CDN that wants manage its power consumption closely. The savings that can be obtained from reducing cooling costs can have a significant impact on the total energy expenditure of a cluster. The key reason is that the energy consumed by cooling equipment is a significant fraction of the energy expended by the IT equipment such as servers. The ratio of total energy to IT energy is a standard metric called PUE (Power Usage Effectiveness) that has a typical value\(^1\) of about 2 implying cooling energy is roughly equal to IT energy in typical data center deployments. But in more recent energy-efficient designs, PUE is smaller but cooling energy is still a significant fraction of the IT energy. Further, cooling energy consumption is not power-proportional since cooling still takes a significant amount of energy even when the servers have low utilization and are not producing much heat, resulting in disproportional energy savings when cooling is shut down entirely (cf. Figure 1a).

Despite these advantages, a cluster shutdown technique is not without disadvantages when compared to server shutdown [9]. Shutting down a cluster and moving all its users to other clusters might degrade performance for users if they have to go “farther away” in the network sense for their content. Further, moving traffic across clusters has the potential of increasing the bandwidth cost, even if it reduces energy. A primary focus of our work then is to evaluate the energy reduction provided by cluster shutdown and how it trades off against potential degradation in performance and increases in bandwidth costs.

B. Our Contributions

We propose algorithms for incorporating cluster shutdown in the GLB of a CDN and quantify the energy savings achievable by this technique. Our evaluation uses extensive real-world traces collected from 22 geographically distributed clusters over 25 days from one of the world’s largest CDNs. We show how energy savings are impacted by the energy characteristics of servers, cooling equipment, and data centers. Further, we quantify the tradeoffs between three goals of

---

\(^{1}\)IT energy expenditure is primarily the energy consumed by the servers, since the networking equipment consume significantly less. Likewise, cooling energy expenditure is dominated by the energy consumed by the chillers [12].

\(^{2}\)In a survey by the Uptime Institute [13] in July 2012, data centers reported an average PUE between 1.8 to 1.89. Other estimates place PUEs even higher.
CDN architecture: saving energy, reducing bandwidth costs, and enhancing end-user performance. Finally, we compare the relative efficacy of cluster shutdown with the well-studied and complementary approach of server shutdown. Our specific key contributions are as follows.

- We propose a GLB algorithm that minimizes energy by routing traffic away from certain clusters and switching them off. On production CDN workloads with typical assumptions for server and cooling efficiencies, our algorithm achieved a significant system-wide reduction in CDN energy consumption of 67%.
- When servers and cooling equipment are energy inefficient, the energy savings from cluster shutdown can be as large as 73%. These savings can decrease to 61% if the servers become perfectly power proportional, and can further become almost zero if the cooling also becomes perfectly efficient.
- The outside air temperature has an impact on cooling efficiency and hence influences the energy savings achievable by cluster shutdown. Energy savings are stable at about 67% for outside temperatures less than 85°F but tapers off as the temperature rises to 44% at 100°F.
- To obtain the maximum possible energy savings, bandwidth costs of the CDN would have to increase by a factor of 2. However, 73% of the maximum energy savings are obtainable with no change in bandwidth costs at all. Likewise, 93% of the maximum energy savings is obtainable with no significant performance degradation with each user served from clusters within a 500 km radius.
- Frequent cluster shutdowns and the operational overheads that it would entail are not necessary to achieve significant energy savings. Our technique is able to extract 79% of the maximum savings even when limiting each cluster to at most one shutdown per day and even when the incoming load is not known in real-time and must be predicted.
- Cluster shutdown does better than server shutdown within a broad operating range of outside air temperatures from 40°F to 90°F, while server shutdown is better outside of this range. In general, cluster shutdown performs better during lower periods of CDN utilization, while server shutdown has the edge at higher utilization.

II. BACKGROUND, MODELS, AND METHODOLOGY

A. Content Delivery Networks

Our work assumes a global content delivery network (CDN) that comprises a very large number of servers that are grouped into thousands of clusters. Each cluster is deployed in a single data center and its size can vary from tens to many thousands of servers. The incoming requests are forwarded to a particular server in a particular cluster by the CDN’s load balancing algorithm. As outlined earlier, load balancing in a CDN is performed in two stages: global load balancing (GLB) that routes a user’s request to an “optimum” cluster, and local load balancing (LLB) that assigns the user request to a specific server within the chosen cluster. Load balancing can be implemented using many mechanisms such as IP Anycast, load balancing switches, or most commonly, the DNS lookup mechanism [3]. We do not assume any particular mechanism, but we do assume that those mechanisms allow load to be arbitrarily re-divided and re-distributed among servers, both within a cluster (local) and across clusters (global). This is a good assumption for typical web workloads that form a significant portion of a CDN’s traffic.

Our proposed technique of cluster shutdown is implemented in the GLB of a CDN. First, GLB moves away all the traffic from a cluster, typically by setting the cluster capacity to zero. Then, the cluster is shutdown by turning off all the relevant components, inclusive of servers and cooling equipment. Since our focus is on GLB algorithms that incorporate cluster shutdown, unless mentioned otherwise, we assume that the LLB evenly distributes the incoming load assigned by the GLB across servers within that cluster. In contrast, the server shutdown mechanism studied in [9] is incorporated within the LLB system that turns off individual servers within a cluster.

B. Workload Model

The workload entering a CDN is generated by users around the world accessing web pages, video content, and Internet-based applications. To model the spatial distribution of the users, we cluster them according to their geographical location. In particular, we define $M$ client locations where each location is a compact geographical area, example, Massachusetts, USA. The workload entering the CDN is modeled as a discrete sequence$^2\lambda_{i,t}, 1 \leq t \leq T$ and $1 \leq i \leq M$, where $\lambda_{i,t}$ is the average load in the $t^{th}$ time slot from users in client location $i$. We always express load in the normalized unit of actual load divided by peak server capacity. Further, we assume that each time slot is $\delta$ seconds long and is large enough for the decisions made by the global load balancing algorithm to take effect. Specifically, in our experiments, we consider $\delta = 5$ minutes.

C. Algorithmic Model for Load Balancing

While a real-life load balancing system is complex [3], we model only those aspects of such a system that are critical to energy usage. For simplicity, our load balancing algorithms redistribute the incoming load rather than explicitly route incoming requests from clients to servers. The major determinant of energy usage is the number of clusters that need to remain active (i.e., turned on) at each time slot to effectively serve the incoming load. Unless we mention otherwise, we assume that local load balancer is not energy aware and does not turn servers on and off on its own accord. But, rather, the LLB simply distributes the load assigned to each cluster evenly among the servers in that cluster. However, the GLB is energy aware and can turn clusters on or off. Therefore a cluster is either active with all servers turned on, or inactive with all servers turned off.

At each time slot, an energy aware GLB takes as input the incoming load $\lambda_i, 1 \leq i \leq M$. The global load balancing algorithm of a CDN routes the incoming load from each client location $i$ to clusters that are active at that time step, i.e., GLB determines the values $\mu_{ij}$ that represents the load induced by client location $i$ on a server in the $j^{th}$ cluster, $1 \leq j \leq N$.

$^2$When the time slot is implicit, we often drop the time subscript from our notation. For instance, we describe the incoming load simply $\lambda_i, 1 \leq i \leq M$.

$^3$For simplicity, we assume that the servers in the CDN are homogeneous with identical capacities, though our algorithms and results can be easily extended to the heterogeneous case.
such that
\[ \sum_{1 \leq j \leq N} \mu_{ij} c_j = \lambda_i, \forall i, \]
where \( c_j \) is the number of servers in that cluster. Servers are typically not loaded to capacity. But rather a target load threshold \( \mu_{\text{max}} \), \( 0 < \mu_{\text{max}} \leq 1 \), is set such that the load balancing algorithm attempts to keep the load on each server of the CDN to no more than \( \mu_{\text{max}} \). Mathematically,
\[ \sum_{1 \leq i \leq M} \mu_{ij} \leq \mu_{\text{max}}, \forall j. \]
We assume a typical value of \( \mu_{\text{max}} = 0.75 \) in our work, i.e., the target load for each server is 75% of its capacity.

D. Power consumption of clusters

We model both the power consumed directly by the servers (IT power) and the power consumed for cooling those servers (cooling power). By convention, we indicate power draw for a single server by using a superscript “server”, while variables without that superscript represent the power draw for the entire cluster. Also, note that while we mostly discuss power draw (in Watts), integrating power draws over time provides us the energy consumed (in Joules).

1) IT power model: First, we model the power consumed by a single server as a function of its load. Based on our own testing of typical off-the-shelf server configurations used by CDNs, we use the standard linear model[1] where the power (in Watts) consumed by a server is
\[ P_{\text{IT,server}} = \left[ P_{\text{IT,server}}^{\text{idle}} + (P_{\text{peak}} - P_{\text{IT,server}}^{\text{idle}}) \alpha \right] \lambda \]  \hspace{1cm} (1)
where the load (\( 0 \leq \lambda \leq 1 \)) is the server load, and \( P_{\text{IT,server}} \) is power consumed by the server when it is loaded to its capacity (i.e., \( \lambda = 1 \)). \( P_{\text{IT,server}}^{\text{idle}} \) is the power consumed by an idle server when it has no load (i.e., \( \lambda = 0 \)). We define a quantity \( 0 \leq \alpha \leq 1 \) called the server power proportionality factor where
\[ \alpha = 1 - \frac{P_{\text{IT,server}}}{P_{\text{IT,server}}^{\text{peak}}}. \]
Note that \( \alpha = 1 \) represents a perfectly power proportional server—the ideal case for an energy-efficient server—while \( \alpha = 0 \) represents the opposite extreme. In our empirical work, unless mentioned otherwise, we use \( P_{\text{IT,server}}^{\text{peak}} = 92 \) Watts, \( \alpha = 0.31 \), and \( P_{\text{IT,server}}^{\text{idle}} = 63 \) Watts as typical values based on our measurements of a typical deployed server today. However, we also vary \( \alpha \) over a wide range to study the impact of server power proportionality on our conclusions.

2) Cooling power model: The cooling systems deployed to cool a server cluster consist of a number of components. An air handler transfers heat out of the server room. An air or water based chiller cools down the hot air before it is pumped back into the server room. The coolant, usually a combination of water and glycol\(^3\) is transferred from the chiller to cooling towers that exchange heat with the outside air before returning it back to the chiller. The chiller plant’s compressor accounts for the majority of the cooling cost in most data centers [12].

To make our model assumptions realistic, we use a set of benchmark regression curves provided by the California Energy Commission (CEC) [14] to model our cooling power requirements. Assuming efficient heat exchange at the cooling towers, we take the outside air temperature as a proxy for the temperature of the coolant on return. The power consumed by

\[ P_{\text{COOL}} = \frac{P_{\text{peak}}}{\beta} + C \cdot u^2 \]  \hspace{1cm} (2)

where \( u \) is the utilization of the chiller and the constants \( A, B, \) and \( C \) are dependent on the capacity correction factor (CAP\_FT) and the efficiency correction factor (EIR\_FT) that vary quadratically with the outside air temperature. Given a value for the outside air temperature the constants \( A, B, \) and \( C \) can be derived from the regression curves provided in the CEC manual [14]. It is worth noting that a chiller consumes disproportionately more power at higher utilization than lower ones due to the quadratic nature of the curve. Also, as shown in Figure 1a, as the outside air temperature gets higher the power required \( P_{\text{COOL}} \) gets larger and curve becomes more non-linear and steeper.

The chillers deployed in practice vary greatly in terms of their efficiency, ranging from less efficient older systems to highly efficient next-generation ones. To study this wide variation, we propose a family of chiller models that have the same quadratic functional form for the relationship between utilization and power consumed as the CEC chiller described in Equation 2 but different values for the constants. Specifically, we define a factor \( \beta \) that we call the chiller efficiency factor and each value of \( \beta \) provides a different curve for the chiller power consumption \( P_{\text{COOL}}(\beta) \) as described in the equation below.

\[ P_{\text{COOL}}(\beta) = \frac{P_{\text{peak}}}{\beta} + (A_{\beta} + B_{\beta} \cdot u + C_{\beta} \cdot u^2), \]  \hspace{1cm} (3)

where \( A_{\beta} = \max\{(\beta A + 1 - \beta), 0\}, B_{\beta} = \beta B, \) and \( C_{\beta} = \beta C \).

We study five chillers by setting \( \beta \) to five different values as shown in Figure 1b. The first three curves (\( 0 \leq \beta < 1 \)) represents chillers that are less efficient than CEC’s chiller. As can be seen from Equation 3, the fourth curve with \( \beta = 1 \) models the CEC chiller exactly. And, the fifth curve with \( \beta > 1 \) models a next-generation chiller that is more efficient than the CEC chiller and has power consumption of zero when idle.
where $P_{\text{IT,peak}}$ is the peak IT power of a cluster, $P_{\text{IT}} = c \times P_{\text{IT,peak}}$, given the PUE of the data center in which the cluster is deployed, we determine the peak cooling power $P_{\text{COOL,peak}} = (\text{PUE} - 1) \times P_{\text{IT,peak}}$. Since the chiller removes the heat produced by the servers, the utilization of the chiller $u = \frac{P_{\text{IT}}}{P_{\text{COOL,peak}}}$. Now, given the value of $\beta$ that determines the cooling efficiency, we can compute the total power consumed by the chiller $P_{\text{COOL}}(\beta)$ using Equation 3. The total power $P$ consumed by the cluster is simply the sum of its IT and cooling power:

$$P = P_{\text{IT}} + P_{\text{COOL}}(\beta)$$

Note that the quadratic and non-energy proportional nature of the chiller-based cooling model has interesting implications on cluster and server shutdown techniques. When a server shutdown technique switches off a fraction of the servers within a cluster, the non-energy proportional nature of the curve works “against” it and does not yield a proportional reduction in cooling energy usage, while a full cluster shutdown reduces the cooling costs to zero for that cluster. In contrast, cluster shutdown “packs” the load from a region onto a smaller number of clusters (and turns off the remaining clusters), but the quadratic nature of the curve yields more than linear increase in cooling costs for the clusters that stay on; the higher the cluster utilization due to such packing, the greater the increase in cooling cost due to the quadratic nature of the curve. A similar effect comes into play due to the outside air temperature, where increasing cluster utilization in hotter outside temperature causes a disproportionately larger increase in cooling costs due to the quadratic curve.

### III. GLB Algorithms with Cluster Shutdown

We now describe our algorithm for global load balancing that routes traffic from client locations to clusters while turning clusters on or off with the goal of minimizing the total energy consumed by the CDN. At any given time, the algorithm takes as input the load $\lambda_i$ from each individual client location $i$. Here we make the simplifying assumption that the GLB knows precisely the load that it needs to route at each time step and that it can instantaneously turn clusters on or off to minimize energy usage. This is clearly not strictly true in practice where both sensing the load and shutting down clusters incur a small delay. However, our algorithm provides a baseline on what is achievable with the cluster shutdown technique, leaving a more complex model that incorporates delays for future work.

The output of our algorithm is two-fold. First, it computes a binary variable $u_j$ that indicates whether the $j^{th}$ cluster should be turned on ($u_j = 1$) or turned off ($u_j = 0$) in that time step. Next, it computes a quantity $\mu_{ij}$ that represents the load from client $i$ that must be routed to cluster $j$ at the given time step.

Computing the assignment of load to clusters can be stated as a convex optimization problem as follows. The IT power required by cluster $j$ is

$$p_{\text{IT},j} = c_j \left[ P_{\text{IT,peak}} \times u_j + \sum_{1 \leq i \leq M} (P_{\text{IT,peak}} - P_{\text{IT,peak}}) \mu_{ij} \right],$$

where the value of $u_j$ is used to determine if the cluster is turned on and $P_{\text{IT,peak}}$ should be incurred. The chiller utilization of cluster $j$ can be computed as $u_j = \frac{p_{\text{IT},j}}{P_{\text{COOL,peak}}}$. The corresponding cooling energy for cluster $j$ denoted by $P_{j}^{\text{COOL}}$ can be computed using Equation (3), given the chiller efficiency $\beta$. Our objective function is simply the total power drawn by the CDN summed across all $N$ clusters and is stated below.

$$\min \sum_{1 \leq i \leq N} (p_{\text{IT},j} + \beta_j) \quad (4a)$$

s.t. \hspace{1cm} \sum_{1 \leq i \leq N} \mu_{ij} \leq \lambda_i, \quad \forall i \quad (4b)$$

$$\sum_{1 \leq i \leq M} \mu_{ij} \leq u_j \mu_{\text{max}}, \quad \forall j \quad (4c)$$

The quantities that are varied in the minimization are the output variables $\mu_{ij}$ and $u_j$. Equation 4b ensures that the all of the incoming load at the given time step is assigned to some cluster. Further, Equation 4c ensures that no server is loaded by more than the threshold $\mu_{\text{max}}$. We pick a typical value of $\mu_{\text{max}} = 0.75$ that implies that no server is loaded to more than 75% of its capacity.

Besides the above constraints that always apply, we also study tradeoffs between energy savings, performance and bandwidth costs by adding one or both of the constraints below.

$$\sum_{1 \leq i \leq M} \sum_{1 \leq j \leq N} \mu_{ij} c_{d_{ij}} \leq D, \quad D \geq 0 \quad (5a)$$

$$\sum_{1 \leq i \leq M} B_{ij} \mu_{ij} \leq BW_{\text{max}}(j), \quad \forall j \quad (5b)$$

Equation (5a) states that the average distance between the users and the cluster to which they are assigned (weighted by load) is no more than some specified value $D$, where $d_{ij}$ is the geographical distance between client location $i$ and cluster $j$. For smaller values of $D$, this equation constrains the global load balancer to assign users to server clusters that are proximal to them, so as to ensure good performance. By making $D$ larger, we are loosening the performance requirement by allowing the users to be assigned to clusters that are farther away. We are particularly interested in how the performance requirement $D$ impacts energy savings. Note that as was assumed in earlier work [15], we use geographical proximity as a rough proxy for “network proximity” that governs user performance. Our formulation could equally well accommodate network latency instead of geographical distance without significant changes, though our empirical CDN traces do not provide the required network information for such an evaluation.

A CDN pays for the bandwidth that their deployed servers utilize. Typically, CDNs use 95/5 contracts for paying for their bandwidth use which works as follows [16]. For each cluster $j$, the traffic from the CDN’s servers in the cluster is averaged...
over 5 minute intervals. Then the 95th percentile of those 5-minute averages over the billing interval is computed. The cost of bandwidth for that cluster is proportional to the computed 95th percentile. Since 95th percentile cannot be modeled and constrained within a convex programming framework, we use the maximum value instead as a proxy. Equation (5b) above is used to constrain the maximum bandwidth sent out of cluster $j$ to be no more than $BW_{max}(j)$, hence also constraining the bandwidth cost that is incurred by the CDN in cluster $j$. Choosing higher values for $BW_{max}(j)$ is tantamount to increasing the allowable bandwidth cost at cluster $j$. We use the bandwidth constraint to study the impact of varying the bandwidth costs on energy savings.

Converting the convex program to a mixed integer program (MIP). Note that as currently stated the objective of the optimization function in Equation 4 contains the term $P_{Cool}$ that is quadratic in variables $\mu_{ij}$. However, since MIPs are more tractable than convex programs, we use a linear piecewise approximation of $P_{Cool}$ to rewrite the optimization with only linear constraints. The domain for the function $P_{Cool}(u)$ was split into equal sized segments. For each such segment $[x_i, x_{i+1}]$ we sampled the value of the function at its endpoints $y_i, y_{i+1}$. Computing the slope $m_i$ and intercept $k_i$, the linear approximation between the points $(x, y_i)$ and $(x + 1, y_{i+1})$ takes the form $P_{Cool}(x, y_{i+1})(u) = P_{Cool}(m_i \cdot u + k_i)$. For each such segment we added a constraint

$$P_{Cool}(x_i, y_{i+1}) \geq P_{Cool}(m_i \cdot u + k_i)$$

with cluster $j$ running at a chiller utilization of $u_j = \frac{\mu_{IT} \cdot BW_{peak}}{c_j \cdot \mu_{IT}}$. $P_{Cool}$ is present in the objective and lower bounded by the piecewise linear approximation. The absence of any other constraint on the variable ensures that it equals its lower bound in the optimal solution. Our implementation used 5 linear segments for an approximation error of 0.25% at 85°F.

IV. Evaluation

To evaluate the benefits of integrating cluster shutdown in a CDN’s global load balancer we used extensive CDN traces from Akamai, perhaps the largest commercial CDN, and ran the algorithms presented in Section III. In our experiments, unless otherwise indicated, we model chillers with $\beta = 1$, i.e., the same as CEC’s chiller model, and we assume that the outside air temperature is 85°F. Later, we vary these parameters and show how energy savings vary with different parameter values.

A. Empirical Data from the Akamai Network

We used extensive load traces collected over 25 days from a large set of Akamai clusters deployed in data centers in the US. The 22 clusters captured in our traces are distributed widely within the US and had 15439 servers in total, i.e., a representative sampling of Akamai’s US deployments. Our load traces account for a peak traffic of 800K requests/second and an aggregate of 950 million requests delivered to clients. The traces consist of a snapshot of total load served by each cluster collected every 5-minute interval from Dec 19th 2008 to January 12th 2009, a time period that includes the busy holiday shopping season for e-commerce traffic (Figure 2). In the figure, one may note load variations due to day, night, weekday, weekend, and holidays (such as low load on day no. 8, which was Christmas) Since the clusters are restricted to the US, we also restricted the trace to clients from North America. The trace consists of samples taken every 5 minutes indicating the current load on each cluster, along with a breakup of traffic from each client location. Specifically, for every 5 minutes, we measured the load induced by client location $i$ on cluster $j$ and the corresponding bytes served by cluster $j$ to users in client location $i$, for all relevant pairs of $i$ and $j$. In addition, we also measured the number of servers present and total capacity of each cluster. In the course of our optimization, we assume that the load from a client can be shifted to any cluster as long as the capacity constraints are met and no server is overloaded. Our traces also capture the geographic location (city, state, and country) of both the client location and cluster, which lets us estimate the geographical distance between the users at a particular client and location the cluster from which they are served. The geographical distance computed in this fashion is used as a proxy for performance. The byte information captured in our traces is used to compute the bandwidth usage of the CDN in each cluster that in turn determine the bandwidth costs incurred by the CDN that we study in our work.

B. Overall energy savings

We emulated the GLB-based cluster shutdown algorithm in Section III on the CDN traces described above. The algorithm minimizes the energy consumption of the CDN in each time step by orchestrating which clusters should be on and which clusters should be turned off. Then the total energy consumed by the CDN is computed by adding the energy consumed at each time step across the entire trace. As a basis for comparison, we used as a baseline the energy consumed by the user-to-cluster assignment in the trace with no cluster
shutdown, i.e., all clusters are assumed to be on throughout the trace which is consistent with how CDNs operate today.

The system-wide energy savings that is possible with cluster shutdown incorporated into the CDN’s GLB is 67% in comparison with the baseline where all clusters are always turned on. In performing this analysis, we make typical assumptions about the energy efficiency of the data centers (PUE = 2), servers (α = 0.31) and chillers (β = 1). We also do not constrain performance and bandwidth costs. Therefore, these are the best case savings possible. However, we vary each of these assumptions in subsequent sections to examine how these savings change under different scenarios. To further breakdown the savings, in Figure 3a we show savings obtained by individual server clusters. Savings vary between 37% to 84% with the median cluster saving 63%. Further, most of the savings can be obtained by performing cluster shutdown in a few key clusters. As shown in Figure 3b, applying cluster shutdown to top 45% of the clusters is sufficient to obtain 94% of the optimal energy savings.

D. CDN Power Proportionality

To visualize how server shutdown makes a CDN more power proportional, it is instructive to view the instantaneous power consumption of the entire CDN as a function of its overall utilization. Specifically, in Figure 4b, we plot the CDN’s total power consumption (as a percentage of its peak) and its overall utilization at each time step as a single point of a scatter plot. Note that these plots are the exact analogue of server proportionality described in Equation 1 that relates power to utilization, but computed for the CDN as a whole. A perfectly power proportional system would have all its points aligned along the 45-degree line shown in the figure. The scatter plot of the total CDN power without cluster shutdown deviates from the ideal 45-degree line significantly as the CDN consumes a lot of power even during periods of low utilization during the non-peak hours. However, cluster shutdown makes the scatter plot of the total CDN power much more closely aligned to the ideal 45-degree line, i.e., cluster shutdown makes the CDN significantly more power proportional.

C. Impact of server and cooling efficiency

CDNs operate with a wide range of server hardware and are deployed in a wide range of data center facilities. Further, both server and cooling efficiencies are constantly being improved over time. To capture these effects, we varied the power proportionality factor of the servers (α) as well as the cooling efficiency of the chillers (β) to study how energy savings vary with these parameters (cf., Figure 4a). When both the servers and cooling are energy-inefficient (α = β = 0), the cluster shutdown technique provides the most energy savings of 73%.

As servers become more energy-efficient the idle power usage gets lower, and thus lowers cooling energy. This results in energy savings from cluster shutdown dropping to 61% when servers are perfectly power proportional (α = 1). In fact for any chiller efficiency β, energy savings decrease as servers become more efficient.

Likewise, for any given server efficiency α, increasing cooling efficiency β reduces the energy savings. For perfectly power proportional servers (α = 1) energy savings fall as β increases, dropping from 61% when β = 0 to 19% for β = 1. In the ideal world with highly-efficient servers and cooling, e.g., α = 1 and β > 1, the energy savings from cluster shutdown approaches zero, i.e., if the “hardware” is itself highly-efficient there is no need for an explicit shutdown mechanism to reduce energy.

E. Impact of Outside Air Temperature

The cooling equipment transfers heat from inside the server room to the external atmosphere. Physical laws suggest that the heat transfer rate through convection is larger when the temperature differential between the inside and outside air temperatures are greater. Thus, it takes less energy to cool when the outside temperature is cooler (say, in the winter) than when the outside temperature is hotter (say, in the summer). Further, as we saw in Figure 1a, the required power for cooling rises more sharply in a quadratic fashion with increasing utilization when the outside air temperature is hotter.

The interplay of outside air temperature with cooling power impacts what energy savings are achievable by GLB via cluster shutdown. Specifically, as outside air temperature increases, the cluster (and server) utilization have to be kept low since
there is a greater cooling power penalty associated with higher utilization. Thus, as shown in Figure 5a, at low temperatures the algorithm runs all active servers at the maximum allowed utilization of $\mu_{\text{max}} = 75\%$. At high temperatures cooling costs rise rapidly with utilization, and the optimal solution at $100^\circ F$ corresponds to active servers running at $39\%$ utilization. Note that to continue to serve the same incoming load, a lower cluster (or, server) utilization means more clusters (and, servers) need to remain active. Thus, the fraction of total CDN capacity that is kept active, rises from $27\%$ at low temperatures, to $51\%$ at $100^\circ F$. The increase in active capacity with rising temperatures combined with lower utilization of active servers has a negative impact on savings. Figure 5b shows that energy savings drop from $67\%$ at $85^\circ F$ to $44\%$ at $100^\circ F$. The energy savings achieved by cluster shutdown at different outside air temperatures can also be viewed as a scatter plot of the total CDN power versus its utilization. The scatter plots in Figures 5c and 5d correspond to $85^\circ F$ and $100^\circ F$ respectively. At $85^\circ F$ the best linear fit to the power-utilization curve has a slope of 1.26, closer to the ideal 45-degree line with a slope of 1, i.e., the CDN with cluster shutdown is roughly power proportional. At $100^\circ F$ the slope almost doubles to 2.46.

F. Tradeoff between Energy and Performance

CDNs host a wide range of applications. Some applications such as dynamic web sites are highly sensitive to network latency, with even small increases in latency causing significant degradation in the performance experienced by the user. Other applications such as software downloads are weakly sensitive to latency and can even be performed in the background. As in [15], we use geographical distance as a rough proxy for the network latency between a user and the cluster assigned to that user by GLB. To study the tradeoff between performance requirement and energy savings we add Equation (5a) as a constraint where different latency requirements can be modeled by varying the distance bound $D$. Specifically, larger values of $D$ allow a larger load-weighted average distance between the users and their assigned clusters. Allowing larger user-cluster distances (and latencies) has the effect of degrading performance, but allows for potentially more cluster-shutdown opportunities for GLB and greater power savings. Figure 6 illustrates this tradeoff where setting $D = 300$ km provides 46% of optimal savings. Note that this distance bound is roughly the distance between Boston and New York with network latencies often in the 10-15 ms range that is adequate for even applications with higher latency sensitive. When $D = 500$, one can achieve 93% of the energy savings. This distance bound is roughly the distance between Boston and Philadelphia where typical latencies are in the 20 ms range, suitable for most moderately latency-sensitive applications. Finally, when $D = 795$ km, a suitable limit for weakly latency-sensitive applications such as background downloads, we achieve 99.9% of optimal savings.

G. Tradeoff between Energy and Bandwidth Costs

The operating expenditure (OPEX) of a CDN includes two major components: the energy costs for powering the servers and the bandwidth cost for the traffic from the server clusters to the users. Reducing energy usage by packing traffic into fewer server clusters could cause increased bandwidth usage in those clusters, which in turn could drive up the bandwidth cost at those clusters. The primary question is whether energy savings can be achieved without significant increase in the bandwidth cost. Note that if energy savings are only obtainable by significantly increasing the bandwidth cost, that would serve as a disincentive for a CDN to implement cluster shutdown.

As noted in Section III, the bandwidth cost incurred by the CDN at each cluster can be approximated by the maximum over all 5-minute time slots in the billing period\(^6\) of the average traffic (in Mbps) transmitted in that time slot. We constrain (through Equation (5b)) the maximum bandwidth for each cluster $j$ to be at most $(1 + r)BW_{\text{max}}(j)$, where $BW_{\text{max}}(j)$ is the maximum bandwidth value observed in the trace and $r$ is the BW relaxation factor that determines how much extra bandwidth costs we are willing to allow. Figure 7a shows energy savings relative to optimal as the bandwidth constraints are relaxed by varying $r$. With no increase in bandwidth cost ($r = 0$), cluster shutdown can still achieve 73% of optimal savings. 47% of the total CDN server capacity remains turned on, with active servers running at an average utilization of 48%. Relaxing bandwidth constraints allows active server utilization to rise to $\mu_{\text{max}} = 75\%$ at $r = 1$. This allows the CDN to run with 27% of its server capacity turned on and achieve optimal energy savings. Overall, our results indicate that cluster shutdown can still achieve significant energy savings with little or no increase in bandwidth costs.

H. Impact of Limiting the Cluster Transitions

Frequently switching server clusters on and off can impact the overall lifetime and reliability of the equipment. Further, the mechanical nature of cooling equipment limits the rate at which it can be switched on and off. Chillers, for example,

---

\(^6\)In our simulations, we assume that the billing period is length of the trace which is 25 days, though in reality a billing period is typically one month.
require a warm up at partial load before they can be incrementally ramped up to full capacity. Thus it is neither desirable nor feasible to frequently turn entire clusters on and off, and we study the amount of energy savings that can be extracted when limiting the frequency of cluster shutdowns.

Suppose that cluster transitions are allowed to occur only once every $\tau$ time slots, where $\tau$ is defined as the decision period and is required to be an integral multiple of $\delta$. In our experiments we vary $\tau$ from 5 minutes to 1 day. In Figure 8a the left-most point in the graph corresponds to $\tau = 5$ minutes which is the smallest time granularity at which the trace data is collected. It is nearly infeasible to turn clusters on or off every 5 minutes. However, the $\tau = 5$ minutes measurement provides the theoretical optimal of how much energy savings is possible in the best case that can serve as a benchmark for comparing other values of $\tau$. Increasing $\tau$ could decrease energy savings as GLB has a lesser ability to turn clusters on or off in response to load variations. However, as we see in Figure 8a, even with $\tau = 1$ day where clusters are transitions just once a day, we achieve 80% of the optimal savings possible. Thus, we establish that frequent cluster transitions are not necessary for obtaining most of the benefits of cluster shutdown.

I. Impact of inaccurate real-time load information

Thus far, we have assumed that the load for the current decision period $\tau$ is accurately available and can be used for decision making for that period. This is a reasonable assumption for smaller decision periods (say $\tau \leq 30$ minutes) but not so much when the decisions are more infrequent and decision periods are longer. Therefore we consider the situation where our algorithm does not know the current load but would have to predict it for the purpose of deciding which clusters are transitioned. When cluster transitions are made based on a prediction of load over any extent of time there always exists the chance of insufficient active capacity and users being denied service. We allow active CDN clusters to run to 100% utilization before they drop incoming workload. We define availability as the ratio of workload served to total workload. Under these assumptions, we define a simple algorithm that predicts the load and computes the optimal cluster allocation under this prediction. The predicted load equals the load at the previous decision period, for small decision periods ($\tau \leq 1$ hour), or the load at the same decision period from the previous day, for larger periods ($\tau > 1$ hour). Using this simple prediction algorithm, Figure 8b shows energy savings for decision period 5 minutes $\leq \tau \leq 1$ day. Energy savings dropped from 100% to 79% of optimal over this range. In each case, the algorithm provided at least “three nines” of availability (i.e. 99.9%).

J. Cluster vs Server shutdown

We look at the relative energy savings of two complementary techniques: GLB that incorporates cluster shutdown and an LLB that incorporates server shutdown. We assume that LLB always keeps the exact number of servers required to serve the incoming load for every cluster and at every time step. This is of course an optimistic assumption but it helps understand the best possible savings achievable using LLB. However, unlike GLB, LLB is unable to move traffic across clusters to shutdown entire clusters. Figure 9 plots the difference between the energy savings of implementing cluster shutdown in GLB and the corresponding savings from implementing server shutdown in LLB. In Figure 9a, we see that at low outside air temperatures when cooling is relatively inexpensive (cf., Fig 1a), LLB with server shutdown performs better due to its greater impact on server energy. At high temperatures GLB with cluster shutdown runs active clusters at lower utilization to reduce cooling energy. The limited ability of GLB to shutdown clusters at higher temperatures implies that it performs worse than LLB. Thus, GLB outperforms LLB at moderate temperatures outside of these two extremes. The relative performance of GLB versus LLB also depends on the CDN utilization. Figure 9b shows that when the CDN is lightly loaded, GLB has greater flexibility to move traffic around and switch off clusters. There are fewer such opportunities at higher system utilization, where larger clusters need to be kept active for serving the incoming CDN load. At 85°F, the trend is reversed and LLB performs better. But the additional energy savings drop from 42% to 4% as CDN utilization increases from 7% to 35%. This trend is exaggerated when the temperature increases to 100°F. In this case, LLB is better than GLB but the additional savings provided by LLB increases from 9% to 68% over the same range of utilization.
management techniques have been studied in [23]. Thermal-aware workload placement techniques that place load on cool portions of the data center have been studied in [24], [25]. Models for air- or chiller-based cooling data centers have been studied in [23], [26]; the cooling models used in our paper are inspired by this work and also the data published by the California Energy Commission [14].

A key difference between the prior work and our work is our focus on content delivery networks: the design choices made by a CDN require these ideas to be customized to the CDN case, for instance by integrating energy management with the CDN’s load balancing algorithms. Another key CDN-specific issue is to design energy saving methods that minimize the impact on user performance and bandwidth costs. Specifically we use realistic power and cooling models for clusters, based on prior work, and use them to design cluster shutdown algorithms that can be implemented in the CDN’s global load balancing algorithms. In this sense the approach also differs from, and is complementary to, prior work on server shutdown technique for CDN energy management [9].

VI. CONCLUSIONS

We focused on the design of energy-efficient CDNs. Since a CDN could comprise thousands of server clusters across the globe consuming a significant amount of energy, we propose a new technique called cluster shutdown to turn off entire clusters to save energy. Our experimental results using extensive traces from a commercial CDN shows that cluster shutdown can reduce system-wide energy usage by 67% in the optimal case, and most of these savings can be achieved without sacrificing end-user performance and bandwidth costs. In addition, the technique works well even when shutdown is limited to once per day for each cluster and when the load is not known in real-time and must be predicted. We believe that cluster shutdown is a strong candidate for implementation in an actual CDN, especially since it fits in more easily with current CDN architectural principles in comparison with server shutdown techniques studied in the past. However, integrating both cluster and server shutdown in a complementary fashion to make both GLB and LLB energy-aware might lead to even greater efficiencies and is an interesting topic for future work.
